We present the design, fabrication and characterization of a compact photodetector suitable for photonic interconnections on electronic ICs. In our approach, the InP-based optical sources and detectors are linked via Si photonic waveguides in an interconnection layer on top of the CMOS circuitry. The photonic device processing is compatible with Si wafer scale fabrication steps, which guarantees compatibility with future ICs manufacture. The detector makes use of an InP membrane waveguide to couple the light out of the interconnection layer and carry it towards the absorption region. A responsivity of 0.45 A/W and a rather flat frequency response in the 0-20 GHz range were measured.

Introduction

For future generation electronic ICs, a bottleneck is expected at the interconnect level. The integration of optical sources, waveguides and detectors forming a photonic interconnect layer on top of the CMOS circuitry is a promising solution, providing bandwidth increase, immunity to EM noise and reduction in power consumption [1]. We investigated this solution within the framework of the European project PICMOS¹ and the Dutch National project Smartmix-Memphis². In our implementation, the interconnect layer is built as a passive Si photonic waveguide layer and the InP-based photonic sources and detectors are fabricated in a way compatible with wafer scale processing steps. This approach combines the advantages of high quality Si wires with the excellent properties of InP-based components for light generation and detection. The integration technique that is investigated here assures compatibility towards future generation electronic ICs and is based on a die-to-wafer molecular bonding technology [2]. Experimental results on a full optical link, including lasers and detectors, were reported in [3]. In this paper, we focus on the photodetector (PD): device design, fabrication and measurement results are presented, including device characterization up to 20 GHz.

Design

In order to detect the light, it first has to be coupled from the Si wire into the PD structure. In our approach, that is realized by means of an InP membrane input waveguide on top

of the SOI wafer containing the Si photonic wiring (see Fig. 1). The two waveguides act as a synchronous coupler that transfers the optical signal from the Si wire into the transparent InP waveguide, which guides it to the PD absorption region stacked on top of the transparent layer. The detector structure has a footprint of $5 \times 10 \mu\text{m}^2$ and is built as an InGaAs absorption layer sandwiched between a highly p-doped InGaAs contact layer and a highly n-doped InP layer, which is also used for realizing the membrane waveguide.

Figure 1: Photodetector structure. The coupling from the Si waveguide layer to the PD is realized via the InP membrane input waveguide, on top of which the detector is stacked. A cross section of the coupler is schematically shown.

The PD 3-dB bandwidth is mainly limited by the carrier transit-time, as the RC -time is < 10 ps, thanks to the compact device dimensions. Fig. 2 (left) shows the calculated transit-time frequency response for a p-i-n photodiode which employs our layer stack. The curves are calculated by solving the carrier rate equations under the hypothesis of uniform and exponential carrier generation in the illuminated intrinsic diode region, as explained in detail in [4]. In our case, the heterojunction is bottom-illuminated and the carriers are generated close to the n-side (see Fig. 1). That leads to an expected transit-time limited bandwidth of about 30 GHz, as it can be read from Fig. 2 (left). Following the hypothesis of uniform carrier generation, for simplicity, the transit-time frequency 3-dB point dependence on the PD absorption layer thickness was calculated (see Fig. 2, right). Clearly, there is trade-off between device speed and efficiency: the thicker the absorption layer, the higher the efficiency and the lower the bandwidth. Simulation results show that an internal quantum efficiency somewhat $< 90\%$ is expected for a total detector thickness of $1 \mu\text{m}$, corresponding to an absorption layer thickness of 700 nm, as we reported in [5]. Such choice for the device thickness was driven by the ease of integration with the μ -disk lasers, as described in [3].

The detector input InP coupler was designed with a cross section geometry of $0.25 \times 1 \mu\text{m}^2$ and a length of $14 \mu\text{m}$ to achieve mode matching with the Si photonic waveguide, which is $500 \times 220 \text{ nm}^2$ [5]. Details about design, fabrication and characterization of the Si waveguides are extensively presented in [6].

Fabrication

The PD layer stack was grown on a 2" InP wafer. It was sawn in dies that were then molecular-bonded upside down on an SOI wafer, in which the Si waveguides had been defined, and the InP substrate was removed from the dies by a combination of chemical-mechanical polishing and wet-chemical etching. Afterwards, the PD pattern was aligned on the Si structures by e-beam lithography and transferred to a SiO_2 hard mask. Then, the SOI wafer was sawn into samples, to allow for processing in our clean room. The PD structure was defined using III-V conventional wet- and dry-etching techniques. A polyimide layer was used to planarize the chip and provide electrical isolation and a Ti/Pt/Au metal stack was evaporated and patterned by lift-off. Si grating fiber couplers

were also integrated in the Si waveguide layer to allow for on-wafer characterization [7]. Fabricated devices are shown in Fig. 3.

Measurement Results

The detector DC characterization was performed by using a tunable laser source (TLS) and a polarization controller to couple TE-polarized light through the grating coupler into the Si waveguide. A source-meter unit was used to reversely bias the PD and to read out the generated photocurrent. The photodiode generated photocurrent as a function of the applied bias voltage was measured for 0, 25 and 50 μW input powers (see Fig. 4, left). A dark current around 1.6 nA was registered at -4 V. The PD responsivity was calculated to be $R = 0.45$ A/W, which is a conservative value, as the grating coupler maximum efficiency was assumed (maximum 20% at 1575 nm). Such responsivity corresponds to a quantum efficiency of 35%, which includes the efficiency of the InP membrane coupler and the internal quantum efficiency of the pin-detector itself. Dynamic measurements were performed in the range of 130 MHz to 20 GHz with an Agilent HP8703A lightwave component analyzer (LCA), used for small signal modulation of the input optical power from the TLS and for reading out the RF electrical signal generated by the PD. Results are

presented in Fig. 4 (right), which shows a rather flat frequency response up to 20 GHz, except for oscillations around 17 GHz, probably due to non-ideal de-embedding of the RF components used in the set-up, and around 2 GHz, caused by the optical module of our LCA, not working properly below that point.

Conclusions and Acknowledgment

We presented a $50\ \mu\text{m}^2$ InP-based photodetector fabricated on samples bonded to an SOI wafer containing Si waveguides, suitable for an optical interconnect layer on top of CMOS ICs. Measurements recorded a responsivity $R=0.45\ \text{A/W}$ and a rather flat frequency response up to 20 GHz.

We acknowledge the support of the EU IST-PICMOS project and the Dutch National Smartmix-Memphis project.
